Conclusions: Patients with APS who undergo PCI have worse long-term clinical outcomes, driven by higher rates of revascularization, than other patients undergoing PCI. Further study is warranted to examine the mechanisms underlying these findings.

Introduction

Antiphospholipid antibody syndrome (APS) is an entity comprising both clinical and laboratory features. Based on the most recent criteria, the definition of APS requires at least one clinical and one laboratory manifestation, i.e. vascular thrombosis (arterial, venous or small vessel thrombosis), pregnancy-related morbidity (an unexplained fetal death after the 10th week of gestation, 3 or more unexplained consecutive spontaneous abortions before the 10th week of gestation or premature birth of a morphologically normal neonate before the 34th week of gestation due to eclampsia or severe preeclampsia) and laboratory parameters, detected at least twice, 12 weeks apart (anticardiolipin, anti-β2-glycoprotein I or lupus anticoagulant) [1].

APS is the most common acquired form of blood protein defect, resulting in both arterial and venous throm-
bolic events [2]. Patients with APS have an increased risk of atherothrombotic complications, such as cerebrovascular and myocardial infarction (MI) [3–6]. Both cerebrovascular and coronary artery diseases are more prevalent in patients with APS and comprise the major cause of mortality and morbidity in these patients [7, 8]. The presence of APS is a strong risk factor for the development of coronary artery disease, especially in young patients [9]. In the Risk of Arterial Thrombosis In Relation to Oral Contraceptives study, the odds ratio for an MI in young women was 5.3 times higher in patients with lupus anticoagulant as compared to other women [10]. The increased risk of premature atherosclerosis and its thrombotic complications is probably caused by proinflammatory and procoagulant effects on vascular endothelial cells, or indirectly via immunoinflammatory mechanisms underlying autoantibody-mediated thrombosis [11–15].

Although the syndrome is known for its vascular complications, many of the cardiovascular aspects of APS remain largely obscure. In particular, there is a paucity of data regarding the outcome of patients with APS who undergo coronary revascularization. Small studies have demonstrated that patients with APS are predisposed to high rates of restenosis of the coronary arteries and vascular grafts after percutaneous coronary intervention (PCI) or coronary artery bypass graft surgery, respectively, causing significant morbidity and mortality [16–19]. Some of these studies were conducted more than a decade ago, in the percutaneous transluminal coronary angioplasty era, and are therefore less relevant for contemporary PCI practice [16, 19]. Other studies did not define and focus on APS patients as a specific study group, but rather included patients with certain antibodies considered part of the syndrome. Also, some of these studies included only patients with secondary APS, such as in the case of APS and systemic lupus erythematosus (SLE). These studies cannot fully shed light on the prognosis of the unique group of patients with APS, both primary and secondary, after revascularization. Therefore, given the paucity of data, we aimed to assess the long-term outcomes of patients with APS who undergo PCI.

**Methods**

The Rabin Medical Center PCI registry was systematically reviewed for patients with a diagnosis of APS who underwent PCI between the years 2003 and 2008. Patients with APS were identified according to the diagnoses listed in their charts. In all cases, we verified that the diagnosis of APS met with current criteria [1]. Clinical manifestations, such as vascular thrombosis or pregnancy-related morbidity, were identified. In addition, two separate positive antiphospholipid antibodies (aPL; anticardiolipin IgG and/or IgM, anti-β2-glycoprotein I IgG and/or IgM or lupus anticoagulant) were required for APS diagnosis and inclusion in the study. After careful selection, 19 patients with confirmed APS were identified. Sixteen of them were classified as primary APS, and 3 were diagnosed with SLE, and therefore had secondary APS. For each patient with APS, 20 control non-APS patients who underwent PCI during the same period were matched by age (±5 years), gender, diabetes mellitus and hypertension.

The control group was identified from the Rabin Medical Center PCI registry, which is a comprehensive database which processes all the data regarding all consecutive cases of PCI from 2003 and onwards performed at the two hospitals of the Rabin Medical Center. It includes all the procedural data, as well as clinical, laboratory, echocardiographic and subsequent event data, from several sources, i.e. the patients’ electronic medical record system, the medical centers’ demographic information system, the medical centers’ data warehouse and the medical centers’ central laboratory database. Data are periodically integrated, reviewed, checked for accuracy and analyzed. Data collection was approved by the hospital ethics committee in compliance with the Declaration of Helsinki, with waiver for the need of individual informed consent.

Since the majority of the patients in the APS group had undergone PCI because of an acute coronary syndrome (ACS), and in order to enable comparison to a high-risk group, a secondary analysis was performed in which the APS group was compared to patients with ST segment elevation MI (STEMI) who were treated with PCI. For this purpose, we used the Rabin Medical Center’s STEMI primary PCI registry, which is a prospective registry of consecutive patients with STEMI who underwent primary PCI at the Rabin Medical Center between the years 2003 and 2008. The registry includes demographic, clinical, angiographic and procedural data. Immediate and in-hospital events are recorded from the hospital charts. For each patient, a standardized questionnaire is completed either by telephone or in the outpatient clinic at 6 months and yearly thereafter. A total of 1,458 patients with STEMI were included in the present study as the second control group (after excluding the APS patients and patients with cardiogenic shock).

For all groups, accuracy of the mortality data was verified with the Israel Central Bureau of Statistics, Interior Ministry of Israel. All data regarding patients’ prior and subsequent hospitalizations, including all ICD-9 diagnoses, were retrieved from the medical centers’ data warehouse. Repeated revascularization procedures and episodes of MI were confirmed using the hospital and affiliated hospital databases.

All patients (in all groups) were treated with aspirin before the PCI and clopidogrel (300–600 mg) either before PCI (pretreatment) or immediately after the procedure. Unfractionated heparin (70 U/kg loading) was given before PCI, and the dosage was adjusted to achieve an activated clotting time of 200–250 s during the intervention. Glycoprotein IIb/IIIa receptor inhibition by eptifibatide was used at the discretion of the operator. All patients were prescribed lifelong aspirin and clopidogrel (75 mg/day) for 3–12 months, depending on stent type.

Acute STEMI was defined as the presence of typical chest pain and accompanying symptoms for ≥30 min but <12 h in the pres-
ence of ST segment elevation ≥1 mm in ≥2 contiguous leads or new or undetermined duration of left branch bundle block in association with ≥2-fold increase in cardiac enzymes (troponin I or T). The diagnosis of (re-)infarction during follow-up was based on recurrent chest pain suggestive of an acute MI, accompanied by a repeated increase in cardiac enzymes to ≥2 times the upper limit of normal ≥48 h after PCI and/or new ST elevation or pathologic Q wave on surface electrocardiography. Target vessel revascularization (TVR) was defined as any revascularization that involved the target vessel. Major adverse cardiac events (MACE) included any of the following (without repetition): death, nonfatal MI or TVR. All events were further adjudicated by a research coordinator and reviewed by an experienced cardiologist from our research team. Follow-up was completed for 100% of the patients and the PCI group (table 1). The only discrepancies that remained after matching were higher rates of left ventricular dysfunction and hyperlipidemia in patients with APS (table 1). Patients with APS were also compared to the STEMI group in secondary analysis (table 2). In this latter comparison, patients with APS were more likely to be women, have hypertension and hyperlipidemia and be treated with statins than patients with STEMI. In addition, they had higher rates of stroke and coronary artery bypass surgery in the past. The indication for PCI among the patients with APS was an ACS in 10 patients (52.6%, including 31.6% with acute MI and 21% with recent MI or unstable angina). The rest of the patients were treated for stable angina. All patients with APS were treated with Coumadin (warfarin) before and after the PCI. However, the international normalized ratio (INR) at admission was above 1.5 in only 37% of the patients.

### Results

Clinical characteristics of the APS group and the two control groups are presented in tables 1 and 2. Because of disparities in clinical characteristics, matching was performed according to gender, age, diabetes and hypertension status, with a ratio of 1:20 between the APS patients and the PCI group (table 1). The only discrepancies that remained after matching were higher rates of left ventricular dysfunction and hyperlipidemia in patients with APS (table 1). Patients with APS were also compared to the STEMI group in secondary analysis (table 2). In this latter comparison, patients with APS were more likely to be women, have hypertension and hyperlipidemia and be treated with statins than patients with STEMI. In addition, they had higher rates of stroke and coronary artery bypass surgery in the past. The indication for PCI among the patients with APS was an ACS in 10 patients (52.6%, including 31.6% with acute MI and 21% with recent MI or unstable angina). The rest of the patients were treated for stable angina. All patients with APS were treated with Coumadin (warfarin) before and after the PCI. However, the international normalized ratio (INR) at admission was above 1.5 in only 37% of the patients.

Eight patients with APS (42.1%) received clopidogrel before the PCI (mostly because of history of stroke), and they all continued to receive long-term clopidogrel treatment after the procedure. The other patients in the group generally received clopidogrel for 3–12 months after the PCI, depending on the presentation (A CS or stable angina) and the type of stent implanted during the procedure. In the PCI group, patients generally received clopidogrel for 3–12 months, depending on stent type, and in the STEMI group, the majority of the patients received clopidogrel for 1 year following the PCI. All patients received long-term aspirin after the procedure. Angiographic and procedural characteristics of the index procedure were similar between the 2 groups (table 3), including the frequency of the left anterior descending artery as the culprit vessel, the presence of multivessel disease, stent characteristics and infrequent use of drug-eluting stents.

Clinical outcomes of the groups are presented in tables 4 and 5. Data are presented with reference to the follow-up rates at the beginning of each period. Patient follow-up reached 4 years (fig. 1). As compared to the general PCI group, patients with APS had higher rates of TVR, beginning at 6 months of follow-up and onwards, which translated to higher rates of MACE, a difference that had become significant after 1 year. The groups did not differ with regard to rates of MI or mortality (fig. 1; table 4). Data are shown both according to outcomes in each time period and according to the time periods.
Discussion

The current study assessed the long-term outcomes of patients with APS who had undergone PCI. Patients with APS were compared to a matched group of patients without APS who underwent PCI, and also to a high-risk group of patients with STEMI treated by PCI. We found that patients with APS had higher long-term rates of adverse cardiac events when compared to both the general PCI and the STEMI groups. This difference was driven by exceedingly high rates of revascularization in the APS group. Unexpectedly, ischemic complications did not differ between the groups.

The most striking finding of our study are the remarkably high rates of TVR in patients with APS who have undergone PCI, despite similar use of drug-eluting stents and similar diabetes status as the control groups. These revascularization procedures were probably caused by both restenosis within the stent(s) and accelerated atherosclerosis in vessel areas not covered by stents.

An increased risk of restenosis in patients with APS who undergo PCI has been reported previously in a few small studies. Gürel et al. [18] reported a strong association between the levels of anticardiolipin antibodies and the outcome of PCI after an ACS. In this study, higher levels of anticardiolipin antibodies predicted increased rates of restenosis after PCI, without an effect on mortality. Similarly, in the percutaneous transluminal coronary angioplasty era, Eber et al. [19] reported higher rates of restenosis after PCI (with balloon angioplasty) in patients with higher levels of anticardiolipin. The presence of APS also appears to be associated with an increased risk of vein graft disease after coronary artery bypass graft. In...
fact, the risk for accelerated vein graft disease and failure has been shown to correlate well with the levels of anticoagulant antibodies [20, 21]. Thus, our findings, taken together with previous reports, indicate that the presence of APS is a strong risk factor for the development of stent restenosis as well as vein graft disease. Evidence also exists in regards to enhanced atherosclerosis progression and premature ischemic heart disease in patients with APS. Ames et al. [22] reported that levels of IgG anticoagulant independently predict the carotid artery intima-media thickness. Moreover, previous reports have linked levels of anticoagulant with both the risk and extent of peripheral vascular disease [23, 24] and the risk of MI and cardiac death [25].

The potential causes for increased restenosis rates and accelerated atherosclerosis in patients with APS are numerous. A direct pathophysiological effect of aPL on coronary artery endothelium has been suggested. Inhibition of endothelial cell production of prostacyclin may cause endothelial dysfunction as well as enhanced platelet aggregation [26]. Another suggested mechanism may include immune complexes formed by aPL autoantibodies, which may deposit in the vessel wall, causing inflammation and wall injury. In addition, β₂-glycoprotein I antibodies are known to activate and damage endothelial cells [27]. These processes all lead to endothelial dysfunction as well as a thrombotic diathesis [26–28]. Secondly, anticoagulant antibodies can potentially cross-react with antibodies against oxidized low-density lipoprotein (LDL), due to similarities between the cardiolipin and β₂-glycoprotein I and LDL molecules [29]. In turn, antibodies against oxidized LDL have been clearly linked to accelerated atherosclerosis progression [30]. Thirdly, aPL may potentially promote local intimal smooth muscle cell proliferation and restenosis indirectly, by enhancing the release of cytokines and growth factors [31–33]. Finally, medical treatment and other systemic comorbidities in patients with APS may enhance atherosclerosis and restenosis indirectly, such as in the case of steroid treatment and renal disease in SLE patients. However, in our study group only 3 patients were diagnosed with SLE, and only 1 patient had received steroids at admission and on a regular basis.

Despite the known propensity for thrombotic complications in patients with APS, as well as case reports of recurrent stent thrombosis [34–36], we did not observe differences in the rates of MI or death between the APS and the control groups. This may have been caused by lack of statistical power, as the group of patients with APS was relatively small. Also, it is possible there was a selection bias in the previously diagnosed APS group, since all patients were well treated and under regular medical surveillance before (and after) the index procedure. Most importantly, all the patients with APS were treated with anticoagulation (vitamin K antagonists) before and after the PCI, in addition to antiplatelet therapy. However, as pointed out, while all APS patients were prescribed vitamin K antagonists by their physicians, it seems that compliance rates for therapy were low, as attested by the nontherapeutic INR levels at admission in many of the patients (63%). It is possible that these low rates of therapeutic INR levels on admission may have contributed to the ACS presentation in some of the patients.

The present study has several limitations. Firstly, the APS group is of relatively small size and was compared to a large group of patients, limiting the statistical power of the study. Secondly, there were significant imbalances between the groups, mainly with regard to clinical characteristics. However, following the matching process to the PCI group, most imbalances were resolved. Thirdly, the study was based on a registry, with all the limitations inherent to a nonrandomized trial. Fourthly, we did not have data regarding the exact duration of clopidogrel therapy following PCI in all patients. Finally, our study group mostly comprised patients with primary APS but also included 3 patients with secondary APS. Mechanisms of coronary disease may differ between these two groups. For instance, SLE patients with APS have been shown to have a higher rate of atherosclerotic plaque formation when assessed for intima-media thickness. In primary APS, a causative association between the presence of aPL antibodies and accelerated atherosclerosis is yet to be established [37, 38]. The association between aPL and the increased rates of TVR in our study may be explained by a pathological effect of aPL on the endothelium, leading to endothelial dysfunction and perturbation, and through the induction of a more inflammatory local environment (via cytokines and growth factors), thus overall increasing the risk for restenosis [38].

Despite these limitations, our study highlights the increased risk patients with APS have for long-term complications after PCI and, in particular, the need for revascularization. The clinical implications of this study, as well as of previous reports, are that an early and aggressive approach to the treatment of patients with APS undergoing coronary intervention is warranted. Such an approach may include the administration of high-dose statins and antiplatelet and anticoagulant therapy. However, treatment of these patients before and after PCI poses several therapeutic dilemmas, such as the duration of...
dual antiplatelet therapy in addition to anticoagulation and the choice of bare metal versus drug-eluting stents, balancing the risks of thrombosis and restenosis versus bleeding. Future studies may help guide the therapeutic strategy. In addition, further research examining the mechanisms which underlie the increased rates of restenosis and revascularization in patients with APS is warranted.
